Properties of Mobile Ad hoc Networks ($MANETs$) present major vulnerabilities in security. The threats considered in $MANETs$ may be due to maliciousness of a node that intentionally disrupts the network by using variety of attacks and/or due to selfishness of the node which does not perform certain operations due to a wish to save power. None of the existing algorithms to mitigate black hole attacks handles selfish nodes. We present a first such algorithm which handles blackhole attack as well as selfish nodes. A co-operative security scheme called Reliable Ad hoc On-demand Distance Vector routing protocol has been proposed to solve the problem of attack by Blackhole node as well as Selfish behavior ($RDVBS$). $RDVBS$ behaves like $AODV$ in the absence of attack with only a slight increase in the routing overhead and, detects and isolates black nodes and selfish nodes in the presence of attack. It also recovers from the attack when a black node leaves the network or a selfish node becomes good. Our protocol is also superior to the previous known algorithms in terms of routing overhead. The protocol also handles multiple and cooperative black nodes.

Keywords: Ad hoc Network; Security; Attack; Blackhole; Selfish node

1. INTRODUCTION

Ad-hoc networks [Ramanathan and Redi 2002] have been proposed to support scenarios where no wired infrastructure exists. They can be set up quickly where the existing infrastructure does not meet application requirements for reasons such as security, cost, or quality. Examples of applications for ad hoc networks range from military operations, emergency disaster relief to community networking and interaction between attendees at a meeting or students during a lecture. In Mobile Ad hoc Networks ($MANETs$) each node has limited wireless transmission range, so the routing in $MANETs$ depends on the cooperation of intermediate nodes. Two types of routing protocols have been defined for ad hoc networks: Table-driven protocol and On-demand routing protocol. Table driven protocols are proactive in nature and consume excessive network bandwidth. On the other hand, on demand routing protocol exchange routing information only when needed. Most ad hoc routing protocols rely on implicit trust-your-neighbor relationship to route packets among participating nodes. This naive trust model allows malicious nodes and selfish nodes to paralyze the network. Selfish nodes do not directly damage other nodes but their effect should not be underestimated.

We propose a co-operative security scheme which we call ‘Reliable Distance Vector routing protocol to handle Blackhole and Selfish nodes ($RDVBS$)’ to mitigate attacks by blackhole and selfish nodes. $RDVBS$ provides a foundation for secure operations with little impact on existing protocols and can be used in bandwidth constrained nodes. The existing approaches to assuage the impact of blackhole nodes do not handle selfish nodes and the ones to mitigate selfish nodes do not alleviate the blackhole nodes. In [Khurana et al. 2006], we present a solution to detect blackhole nodes and selfish nodes. However, the paper does not talk of establishing an alternate secure path in case a malicious node is detected. In this work, we present first such approach that detect and isolate the both black hole attack as well as selfish nodes in a single scheme and
establishing an alternate secure path.

The proposed solution mitigates multiple black holes also. We use cross-verification but do not flood the verification packets. The protocol is based on Ad hoc On Demand Vector (AODV) routing protocol with the assumption that nodes cannot impersonate and all other network conditions are good. It behaves like AODV in the absence of attack and, detects and isolates misbehaving nodes in presence of attack. The scheme allows the network to recover from the attack when a misbehaving node leaves the network or becomes good. It does not incur too much overhead as we do not flood the cross-verification packets nor does it require the nodes to listen in promiscuous mode. As the approach is deterministic attacks are detected with 100% success. The protocol does not require any fixed infrastructure as is required to implement virtual banks in incentive based schemes. We compare our algorithm with Deng et al.’s algorithm as it also uses cross-verification and show that our algorithm outperforms theirs in terms of routing overhead without affecting other parameters like end-to-end delay and packet delivery ratio.

For the ease of understanding we present our proposed solution in three phases. Phase I is a slight modification of path-discovery phase of AODV. Instead of keeping one route reply, we keep all the replies so that an alternate secure path can be discovered in case a blackhole node is present on a shortest path. When the source receives a route reply the reliability of the path is checked by sending verification packets in phase-II, reply to which can be generated only by the destination node. If there is a black node on the path, the destination will not receive the control packet (as there is no path from the black node to the destination) and hence no reply would be generated along that path. A secure path is established along the path through which a reply to this packet is received (of course, existence of a secure path is assumed here). Here we point out that the verification packets are not flooded but are multicast to a selected group of nodes (through which route replies were received). Once a path free of black node is discovered, in phase-III, control packets are sent periodically to maintain the reliability of the path, i.e. to detect if any selfish node has crept into the path.

2. PROBLEM STATEMENT

Blackhole attack is an active attack in which a node responds positively to a request for a shortest route even though it does not have a valid route to the destination node. The node is called black node or blackhole node. Since a blackhole node does not have to check its routing table it is the first one to respond to route discovery request in most cases. When data packets reach the black node it drops the packets rather than forwarding them to the destination creating a blackhole there. We call these nodes as blackhole nodes of type 1. Blackhole attack can be co-operative involving multiple nodes acting in coordination with each other.

Bharat Bhargava [Bhargava 2002; Wang et al. 2003] defined blackhole attack as false destination sequence attack also. In this, the blackhole node exploits the fact that the AODV protocol relies on the sequence number of the destination for the freshness of the route; it announces a very high sequence number thus ensuring that its route is considered as freshest and thus gets inserted in the established route. Source considers this path as freshest path and starts sending data packet through it. Again blackhole node drops the packets rather than forwarding them to the destination. We call these nodes as blackhole nodes of type 2.

Sometimes attacks like reducing the amount of routing information available to other nodes, failing to advertise certain routes or discarding routing packets or parts of routing packets are due to selfish behavior of a node. As the supply of power is limited, sometimes a node may wish to use its power supply for its own purposes and hence does not participate in routing operations. Such nodes are called selfish nodes. Selfish nodes were first discussed in [Hollick et al. 2004]. Here we define two types of selfish nodes depending upon their extent of non-cooperation in network operations.

(1) Selfish node of Type 1 uses energy only for its communication and it forwards neither control packets nor data packets.
(2) Selfish node of Type 2 forwards control packets but does not forward data packets. Here we make an assumption that once a node stops forwarding data packets, it does not involve itself into route establishment also. Let \( E \) be the initial maximum energy of a node. When the energy of the node falls within \((T_1, E]\) the node behaves properly and executes both routing functions and packet forwarding. When energy falls in \((T_2, T_1]\) the node forwards control packets but disables data packet forwarding. Since now the node no longer wants to participate in data packet forwarding and its intention is not to disrupt the normal functioning of the network it is legitimate to assume that it will no longer participate in route establishment until its energy is restored. With in a limited time interval the node is recharged and its energy level is set back to the initial value.

3. IMPACT OF BLACKHOLE AND SELFISH NODES

Once a route is established through a blackhole node, it drops the data packets as it does not have a valid path to the destination. As a result the network throughput degrades considerably. Parsons et al. [Parsons and Ebinger 2009] showed the impact of various attacks on AODV. In particular they showed that Packet Loss Ratio (PLR) increases from .13 (in the absence of an attack) to more than .5 when a blackhole attacker is present. They also showed that the routing overhead increases significantly as the number of attackers increase. We also observe in our work that the packet delivery ratio (PDR) of AODV falls from .97 (in the absence of attack) to about .24 when an attacker (blackhole node) is present. A blackhole attacker can also drop received routing messages instead of relaying them, as the protocol requires, thereby making the destination unreachable. The attacker can also store the data and perform traffic analysis.

Several authors [Michiardi and Molva 2002b; Kargl et al. 2004] studied the impact of selfish nodes on dynamic source routing (DSR) algorithm. Michiardi et al. [Michiardi and Molva 2002b] showed that the PDR of the algorithm drops by 60% when 50% of the nodes of the network are selfish. Further they pointed out that the PDR degrades by 10% - 15% every time the percentage of selfish nodes increases by 10%. They also showed that end-to-end delay increases linearly with the percentage of selfish nodes in the network. Kargl et al. [Kargl et al. 2004] also showed that the performance (delivery ratio) of DSR degrades significantly as the number of selfish nodes increase.
increase in the network. We studied the impact of presence of selfish nodes on AODV (Figure 2). We show that the packet delivery ratio of AODV drops by about 55% when 50% of nodes are selfish and it degrades by 10%-20% with increase of 10% in the number of selfish nodes.

![Figure 2. Packet Delivery Ratio of AODV with varying percentage of selfish nodes](image)

4. RELATED WORK

Approaches to assuage impact of blackhole attacks either use cross-verification [Deng et al. 2002; Yin and Madria 2006; Ramaswamy et al. 2005; Banerjee 2008; Agrawal et al. 2008] or are based on watchdog mechanism [Marti and Mishra 2000; Patcha and Mishra 2003]. In [Deng et al. 2002] the source node verifies the authenticity of the intermediate node (IN) sending the RouteReply from its nexthop node (NHN). It does so by broadcasting a FurtherRequest packet to the NHN to verify if it has a route to the destination. In [Yin and Madria 2006] instead of the source node, the previous hop node broadcasts a verification packet to the NHN. Most of the approaches using cross-verification flood the verification packets and hence incur a lot of communication overhead. Watchdog mechanisms require the nodes to listen to their neighbor nodes in promiscuous mode. Switching the mode from promiscuous mode to transmit/receive mode is not easy and is error prone [Kargl et al. 2004]. In some approaches [Tamilselvan and Sankaranarayanan 2007; Shurman et al. 2004] the source node waits for some time, collects some paths and selects the one that shares at least one node with at least one more path. It is based on the hypothesis that if two paths share a node, it is unlikely that it is under attack. The approach suffers with the delay in establishing the route besides the fact that the probability of a blackhole node on the path is non-zero. Some researchers have also proposed Intrusion Detection System (IDS) and learning theory approaches to mitigate blackhole attack [Kurosawa et al. 2007; Huang and Lee 2004; Huang et al. 2003; Ruiz et al. 2008]. These approaches are compute-intensive and incur large storage and communication overhead as they collect and analyze large amount of data for anomaly detection. Sun et al. [Sun et al. 2003] proposed a mechanism to mitigate impersonation where an attacker impersonate as the destination to launch a blackhole attack. Some approaches have been proposed to handle blackhole attack launched by specifying false sequence numbers [Bhargava 2002; Kurosawa et al. 2007]. They handle blackhole attack of type 2.

Most of the work to diminish the effect of selfish nodes either propose a reputation based trust system [Wang et al. 2005; Yan et al. 2003] or are based on providing economic incentives. Reputation based systems either rely on first hand information to build reputation or use second-hand information gathered by other nodes. Though using second-hand information results in building the reputation quickly, it suffers with the drawback of spreading rumors. To handle this CORE
Reliable Distance Vector routing protocol to handle Blackhole and Selfish \((RDVBS)\) nodes in Ad hoc Networks (a COllaborative REputation Mechanism) [Michiardi and Molva 2002a] allows sharing of only positive behavior which makes it vulnerable to positive ratings by malicious nodes. By sharing only negative reputation CONFIDANT (Co-operation of Nodes Fairness In Dynamic Ad-hoc Networks) [Buchegger and Boudec 2002a] reduces the false praise but makes the system vulnerable to false accusations. Context-aware detection [Paul and Westhoff 2002] accepts negative advertisement provided it is claimed by some threshold number of nodes else it is considered as misbehavior. It checks false accusations but at the same time also discourages legitimate reporting of misbehavior especially in sparse networks. DRBTS(Distributed Reputation-based Beacon Trust System) [Srinivasan et al. 2006], CONFIDANT [Buchegger and Boudec 2002b], SORI (Secure and Objective Reputation-based Incentive scheme) [He et al. 2004], RPA (Reputation Propagation and Agreement) [Liu and Yang 2002] and RFSN (Reputation-based Framework for High Integrity Sensor Networks) [Ganeriwal and Srivastava 2004] use both positive and negative information but use different weight functions to different type of information. OCEAN (Observation-based Cooperation Enforcement in Ad Hoc Networks) [Bansal and Baker 2003] and Pathrater [Marti and Mishra 2000] use only first hand information to check the rumors but it takes long for the reputation to fall. Whatever be the strategy, reputation based mechanisms either suffer with the danger of spreading rumors or positive ratings by co-operating malicious nodes or gaining high-reputation and trust by a malicious node and staying in the system. Moreover, most of these approaches require neighborhood monitoring in promiscuous mode. Refaei et al. [Refaei et al. 2005] proposed a reputation based trust mechanism which does not depend upon the reputation information exchange but rather takes the feedback from the destination (e.g. by TCP acknowledgement) to raise the reputation index of its next hop neighbor on successful delivery of the packets. The approach suffers with the drawback that the presence of a selfish node down the path may lead to penalizing a good neighbor.

Incentive based schemes treat packet forwarding as a service that can be priced and introduce some form of virtual currency to encourage packet forwarding [Buttyan and Hubaux 2000; 2001; 2003; Jakobsson et al. 2003; Zhong et al. 2003]. [Buttyan and Hubaux 2001] introduces ‘Incentives to co-operate’ scheme which uses a virtual currency called Nuglets in every communication. Nuglets serve as a per-hop payment for every packet forwarding. They are incremented when a node forwards for others and decremented when it sends packets for themselves. Thus a node exhibiting selfish behavior is penalized appropriately. Authors propose two conceptual models for charging the packet forwarding service. In the first one, called Packet Purse Model (PPM) the source of the packet is charged, whereas in the second one, called Packet Trade Model (PTM), the destination is charged. A hybrid solution is the one in which both source and destination are charged according to the requirement. In PPM, the source node loads the packet with a number of nuglets sufficient to reach the destination. Each forwarding node acquires some nuglets from the packet that covers its forwarding costs. The exact number of nuglets charged by the forwarding nodes may depend upon many things including the amount of energy used for the forwarding operation, the current battery status of the forwarding node, and its current number of nuglets. If a packet does not have enough nuglets to be forwarded then it is discarded. In Packet Trade Model, the packet does not carry nuglets, but it is traded for nuglets by intermediate nodes. Each intermediary buys it from the previous one for some nuglets and sells it to the next one for more nuglets. These schemes (incentive based) require tamper-proof hardware so that the correct amount of credit is added or deducted from a node [Buttyan and Hubaux 2000] or require virtual banks [Buttyan and Hubaux 2003; Jakobsson et al. 2003]. There are arguments that tamper-resistant devices in general might be next to impossible to be realized [Anderson and Kuhn 1996; 1997]. Approaches requiring virtual banks need a fixed communication infrastructure to implement the incentive schemes which is not applicable for a pure ad hoc network. Zhong et al. [Zhong et al. 2003] propose a Simple, Cheat-Proof, Credit based \((Sprite)\) mechanism which does not require tamper-proof hardware but requires an infrastructure (Credit Clearance System) to implement credits.

Most of approaches to alleviate blackhole/selfish nodes do not mitigate collaborative/multiple attacks. The existing solutions to handle multiple/collaborative attacks are either based on Intrusion Detection System (IDS) [Bhargava et al. 2009; Kurosawa et al. 2007; Huang and Lee 2004; Huang et al. 2003; Ruiz et al. 2008] or are recursive application [Ramaswamy et al. 2005] of the approach proposed for a single attack. These approaches handle only a single type of attack. To the best of our knowledge, no algorithm handles more than one type of attack in a single scheme. Handling more than one type of attack in a single scheme is a major challenge for researchers. Bhargava [Bhargava et al. 2009] in their work have suggested a scheme to classify the attacks on the basis of observed behavior and then take corrective measures accordingly.

5. **RDVB: RELIABLE DISTANCE VECTOR ROUTING PROTOCOL TO HANDLE BLACKHOLE ATTACK**

In this section we present an algorithm that assuages only blackhole node. Reliable distance vector routing protocol to handle blackhole (RDVB) is based on AODV routing protocol. After a path has been discovered in AODV, instead of immediately sending out data packets, we check the reliability of the path by sending a verification packet on the discovered path, the reply to which can be generated only by the destination. If there is a blackhole on the discovered path the verification packet will not reach the destination as the blackhole node does not have a path to the destination. When the source node does not receive a reply within a fixed amount of time, it discards the route. Path discovery in RDVB can be thought of as consisting of two phases. Phase I is a slight modification of path-discovery in AODV. In phase-II, we use two control packets called Reliable Route Discovery Unit (RRDU) and RRDU reply (RRDU,REP) to check the reliability of path.

5.1 Phase-I of Algorithm

When a node wishes to communicate with another node it looks for a route from its table. If a valid entry is found for the destination it uses that path to send data packets else it broadcasts a RouteRequest packet (RREQ) to its neighbors with hopcount set to 1. Neighbors check their routing tables for a fresh entry to the destination. If it is found, it replies with a RouteReply (RREP) packet else forwards RREQ to its neighbors with hopcount incremented by 1. The process continues until either the destination or an intermediate node with a fresh route to the destination is located. At each intermediate node a reverse path is created for the source. When the RREQ packet reaches the destination it also replies with an RREP packet. Processing of RREQ at an intermediate node and destination are explained in Figures 16 and 17 respectively.

Since intermediate nodes as well as destination send RREPs in response to RREQ packets, source node as well as intermediate nodes may receive multiple RREPs in the process. In AODV source or intermediate node receiving multiple RREPs selects the one that arrives first and others are discarded. Hence, one unique path is established between the source and the destination. However, in RDVB, a node receiving multiple RREPs maintains a list of next hops in its routing table. When an intermediate node receives an RREP it appends the next hop (NH) node to the next hop list (NHL). NHL is used to discover a new path free from a malicious node in phase-II. In AODV, when the source node receives RREP packet, route is established whereas RDVB enters phase-II. Processing of RREP at an intermediate node and at the source are explained in Figures 18 and 19 respectively. Algorithm 1 summarizes phase-I of algorithm.

The format of Routing Table entry in RDVB is almost the same as that of AODV except for the NH entry. Next Hop entry in the table is now a list of next hops. Formats of AODV routing table entry, RDVB routing table entry, RREQ and RREP are shown below:

1.1 Source broadcasts an RREQ packet.

1.2 When an intermediate node (IN) receives the RREQ packet, it checks its routing table:

   if (the node has a fresh route to destination) then
   
   it replies with an RREP packet.

   else
   
   it broadcasts RREQ further to its neighbors.

   end

1.3 When the destination receives an RREQ, it also replies with an RREP packet.

1.4 When an intermediate node receives the RREP, it appends the next hop to its NHL and forwards the RREP packet on the reverse route.

1.5 When the source node receives the RREP packet it enters phase -II.

**Algorithm 1**: Phase-I of RDVB

5.2 Phase-II of Algorithm

AODV has been extended to RDVB by adding two types of control packets: Reliable Route Discovery Unit (RRDU) and RRDU reply (RRDU_REP). RRDU messages are control packets sent by the source node and RRDU_REP message is the response of RRDU by the destination to the source node. RRDU_REP can only be generated by the destination. We assume that there is no impersonation i.e. no node other than the destination can generate RRDU_REP on behalf of the destination. In phase-II when the source node receives an RREP, it sends a RRDU packet with hopcount set to 1 on the path to check its reliability. If the source node receives multiple RREPs, it sends out an RRDU packet to each of the node from which it receives the RREP packet. The path from which it receives the reply to RRDU is finally established as a reliable path.

When an intermediate node receives an RRDU packet, it forwards RRDU to all the nodes in its NHL with hopcount incremented by one. It also keeps a copy of RRDU for the future RREPs. It keeps on sending RRDUs to the nodes from which it receives RREPs until it receives an RRDU_REP packet. For example, in Figure 1, suppose A receives the first RREP from BH and forwards to s. After this, it receives RREP from B1 and adds it to NHL. When it receives RRDU from s, it sends RRDU to nodes in NHL i.e to BH and B1. It also keeps a copy of RRDU packet. Later when it receives RREP from C1, it adds this to NHL and forwards the copy of RRDU to it. Destination may also receive multiple RREPs, it responds with an RRDU_REP packet (with hopcount set to 1) to the one that arrives first and discards future RRDU packets as duplicates. Thus each node including the source node receives a unique RRDU_REP and a secure path is established. Each intermediate node keeps only the node from which it receives the RRDU_REP in the NHL and discards all other entries from the list. It copies the hopcount from the RRDU_REP packet in the routing table entry for the destination, increments the hopcount in the packet by 1 and forwards the packet on the reverse route. Algorithm 2 summarizes phase-II of RDVB.
2.1 When the source node receives a RREP packet it sends out an RRDU packet with hopcount set to 1 to check the reliability of the path.

2.2 When an intermediate node receives the RRDU packet it increments the hopcount in the packet by one, forwards it to all the nodes in its NHL and keep a copy for future RREPs.

/* Notice here that if we did not keep this list and forwarded the RRDU packet only to the node from which it received the first RREP and that path had a blackhole node, we had no way to discover a path free from the malicious node. We would have known that the path discovered was under attack but would not have been able to discover an alternate reliable path. */

2.3 When the destination receives the RRDU packet it replies with an RRDU REP packet, hopcount set 1, to the first RRDU it receives. It discards the RRDU packets it receives in future as duplicates.

2.4 RRDU REP travels a reliable path back to the source node and the path is established.

Algorithm 2: Phase-II of RDVB

Processing of RRDU and RRDU REP are explained in Figures 20, 21 and 22. Formats of RRDU and RRDU REP messages are shown below:

<table>
<thead>
<tr>
<th>RRDU Message Format</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
</thead>
<tbody>
<tr>
<td>Type</td>
</tr>
</tbody>
</table>

As in AODV, RDVB uses RERR and HELLO messages for route maintenance.

5.3 Security Analysis: handling blackhole attack

In this section we will show that our scheme discovers a path free from blackhole node. See Figure 1. If BH is a malicious node then it may send RREP without having a route to the destination declaring that it has a fresh route to the destination. In case of AODV, if A receives the first RREP from BH, it keeps the path through BH and discards others if the hopcount of others is more. Hence a path through BH is set up between the source and the destination. In RDVB, we send RRDU on this path to check the reliability of the path. Suppose A receives RREPs first from BH, then subsequently from B1 (an intermediate node with path), and then from C1 (RREP received through path C1 - C2 - C3 - C4 - t). It forwards the first RREP to the source. Later when A receives RREPs from B1 and C1, it stores their ids in NHL and discards the RREP packets. When the source receives the RREP packet, it sends RRDU to A. A forwards RRDU to BH, B1 and C1. However, since no node other than the destination can generate a reply to RRDU, A does not receive RRDU REP from BH. Suppose t receives RRDU first from C4 as it is on a shorter route and then from B3. It sends RRDU REP to C4 and discards the RRDU from B3. Thus A receives RRDU REP from C1 via C1 - C2 - C3 - C4 - t, it sets C1 as next hop on the path to t and forwards RRDU REP to s. When s receives RRDU REP a secure reliable path, free from blackhole, is established.

6. RDVB: RELIABLE DISTANCE VECTOR ROUTING PROTOCOL TO HANDLE ATTACKS DUE TO BLACKHOLE AND SELFISH NODES

Consider a selfish node of type 1 i.e. a selfish node that forwards neither the control packets nor the data packets. Such a node will be isolated in RDVB as it will not forward RRDU packet and hence RRDU REP will not be received through it. However, if there is a selfish node of type 2 i.e. a node forwards all control packets including RRDU and RRDU REP but does not cooperate in forwarding data packets, RDVB will not be able to avoid it and hence the above algorithm in its current form will not be able to isolate such a node. Also, a node on the discovered path may co-operate in forwarding data packets for some time and may become
selfish after some time due to its reduced energy levels. In order to identify such a behavior we modify \textit{RDVB} and call it as Reliable Distance Vector routing algorithm for Handling Blackhole and Selfish nodes (\textit{RDVBS}). Path discovery in \textit{RDVBS} is same as that in \textit{RDVB}. However once a path free from black node has been discovered, \textit{RRDUs} are sent periodically to maintain the reliability of the path, i.e. to detect if any misbehaving selfish node has crept into the path. We call this as phase-III of the algorithm.

6.1 Phase-III of Algorithm

To maintain the reliability of the path we introduce a field called Forward Data Packet Count (\textit{FDPC}) in the routing table (\textit{RT}) entry as well as in the \textit{RRDU.REP} packet and a field called Reliability Flag (\textit{RF}) in the \textit{RRDU.REP} packet. Initially \textit{RF} is set to 1 by the destination and it is cleared when a selfish node is detected on the path. \textit{FDPC} in the routing table entry keeps a count of the number of data packets forwarded by the node. For every data packet received and forwarded by a node, \textit{FDPC} in \textit{RT} entry of the node is incremented. This \textit{FDPC} is copied by the node, on return, in the \textit{RRDU.REP} packet to tell its previous neighbor as to how many data packets it has forwarded. The neighbor uses this count to detect whether the node has forwarded all the packets or not. If a node discovers that its next hop neighbor has not forwarded all the packets, it informs the sender by clearing the reliability flag in the \textit{RRDU.REP} packet. Since the selfish node of type 2 participate in forwarding all control packets except the ones used for discovery of path (\textit{RREQs} and \textit{RREPs}) it forwards the \textit{RRDU.REP} packet and since it does not intend to disrupt the normal functioning of the system, it does not lie. In case a selfish node is detected on the discovered path, a fresh route discovery is initiated by the source. Since we assume that once a node starts dropping the data packets, it does not participate in route establishment until its energy is restored, the selfish node is isolated when fresh route discovery is initiated.

A node keeps an entry for each destination in its routing table. In \textit{RDVB}, the routing table entry for destination \textit{t} does not depend upon which source is trying to communicate with \textit{t}. When two source nodes say \textit{s\textsubscript{1}} and \textit{s\textsubscript{2}} try to communicate with \textit{t}, the only thing an intermediate node remembers is the next hop required to reach \textit{t}. But now the node needs to remember how many data packets it has forwarded for each communication. Thus, a list called Reliability List (\textit{RL}) is added in the routing table entry of each node. An entry in the \textit{RL} has source address, Forwarded Data Packet Count (\textit{FDPC}) and \textit{RRDU id}, i.e. the triplet (\textit{Source address}, \textit{FDPC}, \textit{RRDU id}). The triplet entry keeps a count of the number of data packets forwarded by the node from source \textit{s} to the destination \textit{t} since the last \textit{RRDU}. \textit{RRDU id} is incremented every time a new \textit{RRDU} packet is sent by the source. The triplet is initialized when the first \textit{RRDU} is processed in phase-II and, it is used and updated when periodic \textit{RRDUs} are processed in phase-III. Assuming that not too many nodes will be communicating with a given node at a given time, the size of \textit{RL} is not expected to be big. Algorithm 3 summarizes phase-III of the algorithm.

Processing of \textit{RRDU} and \textit{RRDU.REP} in phase-II and phase-III of \textit{RDVBS} is shown in Figures 23, 24, 25 and 26. The format of \textit{RDVBS} routing table entry is same as that of \textit{RDVB} except for the additional \textit{RL} field and the format of \textit{RRDU.REP} is modified to include the reliability flag field. The format of \textit{RDVBS} routing table entry and modified \textit{RRDU.REP} are shown below:

Initialization: RF ← 1, FDPC ← 0

3.1 RRDUs are sent periodically to maintain the reliability of the path.

3.2 When an intermediate node receives a periodic RRDU REP from its next hop neighbor it checks its routing table:
   
   if (next hop neighbor has not forwarded all the packets) then
       it clears the reliability flag in RRDU REP packet and forwards the packet on reverse route.
   else
       it copies FDPC from the RL entry of routing table in the RRDU REP packet and forwards the packet on reverse route.
   end

3.3 When source receives RRDU REP it checks RF in the RRDU REP packet:
   
   if (RF is set to 1) then
       path is considered to be reliable; it sends more data packets, if any.
   else
       it initiates route discovery process again.
   end

Algorithm 3: Phase-III of RDV BS

Note: We can improve the performance of the algorithm slightly by checking if the RREP packet is from the destination itself. If so, it need not send the RRDU packet and it can start sending the data packets on this path without waiting for RRDU REP from the destination.

6.2 Security Analysis: handling selfish nodes

Suppose that the path discovered in Figure 1, is s – A – C₁ – C₂ – C₃ – C₄ – t and let that a node (say C₂) on this path becomes selfish. Let C₂ be a selfish node of type 2 i.e. it forwards control packets but does not forward the data packets. Suppose s sends n data packets to t before sending next RRDU. Then A and C₁ forward all the n data packets to the successor. Let C₂ forwards only p out of the n packets. Then C₃ and C₄ also forward p packets and, the destination receives only p packets. After some time, s sends another RRDU and t sends back the count of the received packets in RRDU REP. FDPC field in the RRDU REP is set to p by the destination. At every node x on the reverse path from the destination to the source, FDPC in RRDU REP is set to the number of data packets forwarded by x on the forward path. Hence, C₄, C₃, and C₂ set FDPC in RRDU REP to p whereas C₁ and A set it to n. When C₁ sees that it had forwarded n packets to C₂ but C₂ forwarded only p (< n) out of them it comes to know that C₂ is selfish and it clears the Reliability Flag in the RRDU REP packet to 0. When the source receives this RRDU REP packet with RF set to zero it knows that something is wrong on this path and it initiates a fresh route discovery. Here we make an assumption that once a node stops forwarding data packets, it does not involve itself into route establishment also. Thus, C₂ discards any RREQ packet received from C₁ and a path ignoring C₂ is established.

The previous set of data packets are sent again.

7. SIMULATION STUDY

We simulated our protocol using Network Simulator [NS2]. To study the performance of RDV BS, packet delivery ratio, average end-to-end delay and routing overhead were studied.

7.1 Simulation Design

Simulation results were obtained for 50 nodes located over 1000m by 1000m region. The traffic sources are CBR (constant bit rate), 512-byte as data packet, sending rate is 1 pkt/sec and with maximum load of 300 packets for one transaction. The node movement speed is varied from 0 to 80 which will be closer to real applications. The mobility are done with pause time 100 second. Script was executed for 300 seconds.
7.2 Simulation Results

We compared the performance of our protocol with that of AODV and DENG in presence of blackhole attack.

Comparison with DENG: Both DENG and RDVBS are able to detect and isolate blackhole node. Average End to End Delay (AEED) and Packet Delivery Ratio (PDR) of RDVBS and DENG are comparable as shown in Figure 3 and 4. Our protocol out performs DENG in terms of Routing Overhead (RO) (see Figure 5). DENG’s route discovery phase comprises of broadcasting route request twice, once for destination and another for intermediate node (for feedback). This leads to the generation of a much more number of RREQ packets than the number of control packets generated in RDVBS.

Comparison with AODV: As expected, Packet Delivery Ratio (PDR) of AODV drops significantly as compared (Figures 4) to RDVBS and DENG in presence of a blackhole node. In the absence of mobility, PDR of AODV is zero whereas that of RDVBS is 1. As the nodes start moving sometimes the blacknode falls on the path and sometimes not. Since RDVBS isolates the blackhole node and AODV does not, PDR of RDVBS remains better than that of AODV whereas the RO of RDVBS is only slightly more than that of AODV which is natural to expect.

Figure 3. Comparison of Average End to End Delay in presence of blackhole node

Figure 4. Comparison of Packet Delivery Ratio in presence of blackhole node
We also compared the performance of our protocol with that of AODV in the presence of selfish nodes.

Comparison with AODV in presence of selfish nodes: As shown in Figure 2, PDR of AODV decrements by 10% - 20% with every 10% increase in the percentage of selfish nodes in network. The figure also shows that when 50% of the nodes of the network are selfish PDR degrades by more than 55%. In RDVBS, as shown in Figure 6, PDR degrades just by 1% - 3% every time the percentage of selfish nodes increases by 10%. On the other hand, AEED and RO (Figures 7 and 8) do not increase much with increase in the number of selfish nodes. Figure 9 shows the impact of mobility on PDR in the presence of selfish nodes. For RDVBS, it is observed that this effect diminishes significantly.
Reliable Distance Vector routing protocol to handle Blackhole and Selfish \((RDVBS)\) nodes in Ad hoc Networks

black nodes, verification step of the route discovery phase of \(RDVBS\) and \(DENG\) lead to some routing overhead (Figure 10). Here also \(RDVBS\) outperforms \(DENG\) whereas \(RO\) of \(RDVBS\) is only slightly more than that of \(AODV\). Packet delivery ratio and average end-to-end delay of

all the three protocols are comparable, see Figure 11 and 12.

Figure. 12. Comparison of Packet Delivery Ratio in absence of blackhole node
8. HANDLING MULTIPLE AND CO-OPERATIVE BLACKHOLE NODES

Our protocol also handles multiple black hole attacks. Consider the scenario in Figure 13. If several \textit{RREPs} are received from all the black nodes present in the network, our protocol sends an \textit{RRDU} packet to all of them. However, no \textit{RRDU.REP} will be received from any black node and hence all the black nodes will be isolated. Also consider the scenario of Figure 14 where
the black nodes co-operate with each other to launch the attack. Such attacks are also detected and isolated by our protocol in a similar way as no \textit{RRDU\_REP} will be received from such a path. \textit{DENNG} will be able to detect multiple attacks of Figure 13 by recursive application thereby incurring a lot of overhead. Also, it will not be able to detect the co-operative attack of Figure 14. In [Tamilselvan and Sankaranarayanan 2007], as the number of co-operating black nodes sending \textit{RREP}s with the same \textit{NHN} increases, the chances of establishing a path through a black node increases.

\textit{Comparison with AODV in presence of multiple black nodes}: Figure 15 shows that the decrease in \textit{PDR} with the increase in the number of black nodes is much less in case of \textit{RDVBS} as compared to that for \textit{AODV}.

9. CONCLUSION
we have presented a first such protocol that handles both black nodes as well as selfish nodes. The protocol is simple to implement, without any special hardware requirement. The protocol outperforms the earlier protocols to handle black nodes in terms of secure path discovery and routing overhead without increasing delays. The protocol handles multiple and cooperative black nodes also.

REFERENCES

When an intermediate node receives an \textit{RREQ} packet from source $s$, it does the following steps:

1. If it has a fresh route to the destination, it replies to the source with \textit{RREP} else it broadcasts (forwards) the \textit{RREQ} packet to its neighbors with hopcount incremented by 1. If additional copies of the same \textit{RREQ} are later received, they are discarded as duplicates.

2. It sets up a reverse path for the reply message.
   
   (a) If it has an entry in its routing table for $s$ but it is not fresh, it refreshes it.
   
   (b) If there is no entry for $s$ in its routing table it creates an entry for $s$ by copying the hopcount and the source id from the \textit{RREQ} packet and, setting the NH field to the address of the neighbor from which the first copy of the broadcast packet is received.

3. If additional copies of the same \textit{RREQ} are later received, they are discarded as duplicates.

Figure 16. Processing of \textit{RREQ} at an intermediate node in RDVB

When the destination receives an \textit{RREQ} packet from source $s$, it does the following steps:

1. If it has an entry in its routing table for $s$ but it is not fresh, it refreshes it.

2. If there is no entry for $s$ in its routing table it creates an entry for $s$ by copying the hopcount and the source id from the \textit{RREQ} packet and, setting the NH field to the address of the neighbor from which the first copy of the broadcast packet is received. It creates an \textit{RREP} packet and unicasts \textit{RREP} to the next hop on the reverse path.

3. If additional copies of the same \textit{RREQ} are later received, they are discarded as duplicates.

Figure 17. Processing of \textit{RREQ} at the destination in RDVB

When an intermediate node receives an \textit{RREP} message, it does the following steps:

1. If it has an entry in its routing table for the destination but it is not fresh, it refreshes it.

2. If it does not have an entry for the destination, it creates an entry for it and sets the NH field to the address of the neighbor from which the packet is received. It forwards it to the next hop on the reverse path.

3. If it already has an entry for the destination (in case of multiple \textit{RREPs}) in its routing table, it appends the next hop from which it received the \textit{RREP} in the NHL entry of the routing table and discards the \textit{RREP} packet. This is required to establish a secure path from blacknode in phase-II of the algorithm.

Figure 18. Processing of \textit{RREP} at an intermediate node in RDVB
When the source node receives an RREP packet, it does the following:

1. If it has an entry in its routing table for the destination but it is not fresh, it refreshes it.
2. If there is no entry for the destination in its routing table it creates an entry for it and sets the NH field to the address of the neighbor from which the packet is received, as the next hop.
3. If it already has a fresh entry for the destination in its routing table (in case of multiple RREPs), it appends the next hop from which it received RREP in NHL entry of the routing table.
4. The node sends an RRDU packet with hopcount set to 1 to the node from which it received the RREP packet and phase-II of the algorithm starts.

Figure 19. Processing of RREP at the source in RDVB

When an intermediate node receives an RRDU packet, it does the following:

1. If there is no reverse path entry for s, it creates an entry for s in its routing table in the same manner as it is done on seeing RREQ (this case may arise when an intermediate node n₁ replies to RREQ with an RREP packet and n₂ is a node on the path from n₁ to t).
2. Each node on the path of RRDU must be having a table entry for the destination. It increments the hopcount in the RRDU packet by 1 and forwards it to all the nodes in NHL.
3. It keeps a copy of RRDU packet for subsequent RREPs.

Figure 20. Processing of RRDU at an intermediate node in RDVB

When the destination receives the RRDU packet, it does the following steps:

1. If there is no reverse path entry for s, it creates an entry for s in its routing table in the same manner as it is done on seeing RREQ.
2. It creates an RRDU_REP packet with hopcount set to 1 and replies to the RRDU which arrives first. It discards the copies of RRDU it receives in future, as duplicates.

Figure 21. Processing of RRDU at the destination in RDVB
When an intermediate node receives an **RRDU REP** packet, it does the following:

1. The node must be having a table entry for the source. It finds next hop on the path from the table entry, and forwards **RRDU REP** to it with hopcount incremented by 1.

2. In a table entry for the destination, it keeps only one entry in the NHL, the one from which it received the **RRDU REP** and deletes others. It copies hop count from the packet in the routing table entry for the destination.

Since no intermediate node can generate **RRDU REP**, source node receives a unique **RRDU REP** and a secure path is established. Source starts sending data packets on this path.

### Phase-II of **RDV BS**

When an intermediate node receives the first **RRDU** packet it does the following:

1. If there is no reverse path entry for \( s \), it creates an entry for \( s \) in its routing table in the same manner as is done on seeing **RREQ**.

2. For the first **RRDU** packet it receives from source \( s \), it appends an entry \((s, 0, 0)\) in RL (i.e. id of the source is copied from the originator field of the **RRDU** packet and, FDPC and **RRDU id** are set to zero). Each node on the path of **RRDU** must be having a table entry for the destination. It forwards **RRDU** with hopcount incremented by 1 to all the nodes in NHL.

3. It keeps a copy of **RRDU** packet for subsequent **RREP**s as in **RDVB**.

### Phase-III of **RDV BS**

When the destination receives the first **RRDU** packet it does the following:

1. If there is no reverse path entry for \( s \), it creates an entry for \( s \) in its routing table in the same manner as it does on seeing **RREQ**.

2. For the first **RRDU** packet it receives from source \( s \), it appends an entry \((s, 0, 0)\) in RL (i.e. id of source is copied from the originator field of the **RRDU** packet and, FDPC, **RRDU id** are set to zero) and it discards the **RRDU** packet.

3. It creates an **RRDU REP** packet with hopcount set to 1 and replies to the node from which the first **RRDU** is received.

### Phase-II of **RDV BS**

When the destination receives a periodic **RRDU** packet it does the following:

1. It creates an **RRDU REP** packet and copies FDPC from the RL list entry to **RRDU REP**. It finds the next hop for \( s \) on the path from table entry and sends **RRDU REP** packet to it.

---

Figure 22. Processing of **RRDU REP** in **RDVB**

Figure 23. Processing of **RRDU** at an intermediate node in **RDVBS**

Figure 24. Processing of **RRDU** at the destination in **RDVBS**
**Phase-II of RDVBS**

When an intermediate node receives the first RRDU REP packet, it finds the next hop for the source from the table entry (on the reverse path) and forwards RRDU REP with hopcount incremented by 1 to it.

**Phase-III of RDVBS**

When an intermediate node receives a periodic RRDU REP packet, it compares FDPC stored in the routing table entry with FDPC in RRDU REP packet; if they are same, it forwards RRDU REP to the next hop on the reverse path else it copies the FDPC value stored in its routing table entry in the RRDU REP packet, clears the reliability flag in the RRDU REP packet and forwards the RRDU REP packet to the next hop on the reverse path.

---

**Figure 25. Processing of RRDU REP at an intermediate node in RDVBS**

**Phase-II of RDVBS**

When the source node receives the first RRDU REP packet, a secure path is discovered and the path is established; it starts sending the data packets on the path.

**Phase-III of RDVBS**

When the source node receives a periodic RRDU REP packet, it checks the RF flag in the packet. If it is set, path is considered to be reliable and it continues sending data packet on that path else it realizes that there is a selfish node on the path and it initiates the route discovery process again.

---
